(Dated: April 24, 2008)

We analyzed the energy and momentum distributions of laser-induced high-energy photoelectrons of alkali and rare gas atoms. For the plateau electrons with energies above $4U_p$, (U_p is the ponderomotive energy), in the tunneling ionization regime, we showed that they originate from the backscattering of laser-induced returning electrons. Using the differential elastic scattering cross sections between the target ion with *free* electrons, we explain experimental observations of whether the plateau electron spectra is flat or steeply descending, and their dependence on species and laser intensity. This quantitative rescattering theory can be used to obtain energy and momentum distributions of plateau electrons without the need of solving the time-dependent Schrödinger equation, but with similar accuracy.

When atoms or molecules are placed in an intense laser pulse, an electron can be released through either a multiphoton or a tunneling mechanism. The distinction is based on the Keldysh parameter $\gamma = \sqrt{I_p/2U_p}$, where I_p is the ionization energy and $U_p = A_0^2/4$ is the ponderomotive energy with A_0 is the peak value of the vector potential. In the multiphoton regime ($\gamma > 1$), the electron spectra exhibit characteristic above-threshold ionization (ATI) peaks separated by photon energy, with yields decreasing monotonically with increasing electron energy [1]. At higher intensities, in the tunneling region ($\gamma < 1$), the spectra are notably different. First, the ionization yield drops steeply from the threshold, but from about 3 or $4U_p$ onward, the yield flattens out significantly until at about $10U_p$ where it drops precipitously again. The flattened spectral region from 4 - $10U_p$ is called the plateau. Similar plateau and cutoff are also well-known in the high-order harmonic generation (HHG). Despite this canonical description, the HHG and electron spectra in the plateau region are not always flat. For electron spectra, earlier experiments show pronounced enhancement in the plateau region in potassium, but not in sodium [2]. Similarly, using nearly identical lasers, clear plateau shows up in Xe target, but not in Kr and Ar [3]. Experimentally the energy spectra of plateau electrons have been observed to depend on laser intensities [4]. The origin of plateau electrons and their dependence on target species and laser intensity is explained in this Letter.

Considerable understanding of laser-induced ATI spectra from atoms has been achieved since 1990's [5, 6, 7]. While the observed spectra in general can be reproduced from solving the time-dependent Schrödinger equation (TDSE) within the single active electron approximation, interpretation of the plateau electrons is based on the

rescattering model. In this model electrons that are released earlier by tunneling ionization can be driven back by the laser field to recollide with the target ion. The plateau electrons are understood to originate from the elastic back scattering of the returning electrons by the target ion. However, existing rescattering model does not predict how they depend on target species and laser intensity. In this Letter we provide such a quantitative rescattering theory (QRS) where the energy and momentum spectra of the plateau electrons can be directly calculated using the elastic scattering cross sections between the target ion and *free* electrons, in combination with laser-induced returning electron wave packet. We also show that the returning electron wave packets depend largely on the laser parameters only. Thus the behavior of the plateau electron spectra is determined *entirely* by the energy and species dependence of the elastic scattering cross sections between the returning electrons and the target ion.

To understand electron energy spectra, we first examine how electron-ion collisions contribute to the photoelectron momentum distributions. In Fig. 1 we show a typical two-dimensional (2D) electron momentum spectra for an atomic target calculated by solving the TDSE [8, 9]. (We use linearly polarized electric field for the laser pulse along the z axis with the carrier-envelope phase set to zero [8]). The horizontal axis is the direction of laser's polarization and the vertical axis is any direction perpendicular to it (the electron spectra has cylindrical symmetry). Due to the short laser pulse, the right-hand side ($p_z > 0$) and the left-hand side ($p_z < 0$) spectra are not symmetric. In Fig. 1, four semi-circles with photoelectron energies of 2, 4, 6 and $10U_p$, respectively, are shown. On the right-hand side, three other

FIG. 1: Typical 2D electron momentum distributions. Photoelectrons with constant energy are given by concentric circles from the origin. The three half circles on the right-hand side depict momentum surfaces resulting from the elastic scattering of returning electrons by the target ion in the presence of a laser field. High-energy electrons are obtained only via large angles backscattering.

semi-circles are given, each with its center shifted along the p_z axis. Each of this circle can be expressed vectorially by $\mathbf{p}_\nu = -A_r \hat{\mathbf{p}}_z + p_r \hat{\mathbf{p}}$. Measured from its own center, the circle maps out the momentum space of the elastically scattered electron with incident momentum p_r . The center is shifted since collision occurs in the presence of the laser field. If the electron-ion collision occurs at time t_r when the vector potential is $\mathbf{A}(t_r) = A_r \hat{\mathbf{p}}_z$, the electron will reach the detector gaining an additional momentum $-A_r$. (Atomic units are used in the above expressions such that the momentum gain in the laser field is directly given by the vector potential A_r .) In the figure, we have chosen the “incident” electrons to be from the right, i.e., with negative p_z . The direction of $\hat{\mathbf{p}}$ and the elastic scattering angles θ are measured from this “incident” direction. This choice would result in high-energy or plateau electrons to emerge with positive p_z after the electron undergoes large-angle backscatterings ($\theta > 90^\circ$). Note that electrons scattered into the forward directions will emerge with low energies. Clearly, similar circles can be drawn for electrons “incident” from the left.

According to the classical model, electrons that return to the ion core at the time when the vector potential is at the peak, A_0 , it will have maximum kinetic energy of $3.17U_p = p_r^2/2$, i.e., with $p_r = 1.26A_0$. If the electron is backscattered by 180° , the emerging photoelectron would have a momentum of $2.26A_0$, or energy of $10U_p$. In a recent paper [10], we examined the photoelectron distributions after the $p_r = 1.26A_0$ electrons have been elastically scattered into the backward directions. The electron yield along this ring (called BRR, or back rescattering ridge) has been shown to be given by

$$I(p_\nu, \theta_\nu) = S(p_r) \sigma(p_r, \theta). \quad (1)$$

This equation is based on the concept of rescattering theory. It states that photoelectron yields along the BRR are proportional to the elastic differential cross section

(DCS), $\sigma(p_r, \theta)$, multiplied by a returning electron wave packet, represented by $S(p_r)$, with the target ion. The validity of Eq. (1) was established in [10] based on accurate TDSE results. Its validity has also been confirmed experimentally in two recent reports [11, 12].

To examine the plateau electrons, elastic scattering by electrons with returning energy less than $3.17U_p$ must be included. These are electrons that return to the parent ion when $A_r = A(t_r)$ is not at the peak. We set the returning electron’s momentum $p_r = 1.26A_r$ and using the rescattering model, Eq. (1). The validity of this model can be checked by comparing the extracted $\sigma(p_r, \theta)$ from the calculated photoelectron momentum spectra $I(p_\nu, \theta_\nu)$, with those directly calculated from electron-ion collisions, as carried out in Morishita *et al.* [10]. Alternatively, we can first use Eq. (1) at an arbitrary angle, say, for photoelectron with momentum vector 10° from the polarization axis, to derive the wave packet $S(p_r)$. We then obtain the rescattering “generated” photoelectron spectra by using Eq. (1). This way we have a quantitative rescattering theory which can be used to obtain the momentum and energy spectra for plateau electrons. We remark later that $S(p_r)$ can also be obtained by other approximations.

In Figs. 2(a,b) electron momentum spectra ($p_z \geq 0$) for sodium and potassium atoms exposed to a 5-cycle laser pulse with wavelength of 3200 nm and peak intensity of 1 TW/cm^2 are presented. On the left-hand half of the 2D plot, the results calculated from TDSE are shown, and on the right-hand half the same distributions obtained from the present QRS model are presented. If the two calculations agree well, then there should exist a good reflection symmetry in the figure. This is clearly the case for each target, confirming the validity of the QRS model at the level of electron momentum distributions for the plateau electrons. In Figs. 2(c,d) the DCS for e- Na^+ and e- K^+ collisions are shown for the range of momenta p_r that contribute to the $4\text{--}10U_p$ photoelectrons. As the collision energy increases, the DCS decreases. However, for the same p_r , the DCS for e- K^+ is about 100 times larger. Furthermore, the angular dependence of the DCS in Fig. 2(c,d) are clearly reflected in the momentum distributions in Figs. 2(a,b). In other words, the elastic scattering cross sections between free electrons and target ion can be “read” out directly from the ATI electron spectra in the momentum space. This is possible because of the other important feature of QRS: the returning electron wave packet $S(p_r)$ depends mostly on the lasers only. This fact has been noted in the high energy region before [13].

From the momentum spectra the ATI energy spectra can be calculated. Since the right-hand side and left-hand side 2D momentum spectra are not symmetric for short pulses, we calculate the energy spectra from each side separately and the sum of them reproduces the whole energy spectra in which the left-hand side makes more

FIG. 2: Single ionization of Na and K atoms by a 5-cycle, $3.2 \mu\text{m}$ infrared laser with peak intensity of $1.0 \times 10^{12} \text{ W/cm}^2$ ($U_p = 0.96 \text{ eV}$). (a,b) Comparison of 2D momentum distributions above $4U_p$ and $p_z \geq 0$ (i.e., half of the momentum space only) obtained from TDSE with those from QRS model. Agreement between the two calculations is indicated by the good reflection symmetry in each figure; (c,d) Elastic differential electron-ion scattering cross sections at large angles; (e) Electron energy spectra calculated from TDSE and those from the QRS model (dotted lines) above $4U_p$ for each target; (f) Experimental electron spectra taken from Gaarde *et al.* [2]. In (e,f) the spectra from the two targets are normalized to each other at low energies.

contribution to the lower energy part. In Fig. 2(e), the results from TDSE and from QRS are compared. We limit the QRS model to electron energy above $4U_p$ only. Clearly the QRS model reproduces the TDSE results well. These calculations can also be compared to the experimental data reported in Gaarde *et al.* [2], as shown in Fig. 2(f). There is a close similarity in the relative yields between our calculations and experiment, even though our calculations used a 5-cycle (20 fs FWHM) pulse while the experiment used somewhat different intensities for a pulse with duration of 1.9 ps. The QRS results clearly establish that the experimental plateau electron spectra for Na and K are due to their elastic scattering cross sections in the momentum range of 0.3 to 0.5. Although it has long been understood (or speculated) that the behavior of plateau electrons are related to elastic scattering cross sections [2, 7], no direct quantitative connection between the two has ever been established until now.

As a side note, we comment that the lower end of the plateau electrons has been set at $4U_p$ in this Letter. According to the classical theory, direct ionization by tunneling (without rescattering) will give maximum electron

FIG. 3: Single ionization of Xe, Kr and Ar atoms by a 5-cycle laser pulse. Except for (c), laser's wavelength is 800 nm and the peak intensity is $I_0 = 1.0 \times 10^{14} \text{ W/cm}^2$ ($A_0 = 0.94$). (a) Comparison of electron energy spectra from TDSE, and from the QRS model above $4U_p$ (chain lines). The QRS energy spectra for Kr and Xe are calculated using the wave packet extracted from Ar, with proper normalization at one energy point; (b) Normalized momentum distributions of the returning electron wave packets extracted from the “left-side” of the momentum spectra; (c) Comparison of Xe plateau electron spectra at different laser intensities and wavelengths, with laser parameters indicated in the figure. Note that the QRS model fails at the lowest intensity; (d,e,f) Differential electron-ion elastic scattering cross sections used in the QRS model.

energy of $2U_p$. Between 2 and $4U_p$, the direct ionization part could still interfere with the rescattering part [13], thus we chose $4U_p$ as the lower end of the QRS model.

We have also studied the plateau electrons for Ar, Kr and Xe atoms. Experimental data for these systems have been reported using lasers of different wavelengths and pulse durations since the 1990's [3, 4]. In fact, the plateau in the high-energy ATI spectra was first observed in Xe. In Fig. 3(a) we show the calculated ATI spectra vs electron energy in units of U_p at the same laser intensity of $1.0 \times 10^{14} \text{ W/cm}^2$ for a five-cycle, 800 nm pulse. In the case of Xe, the plateau is clearly seen – it remains almost constant from $5U_p$ to $10U_p$, while for Kr and Ar, each drops about two to three orders of magnitude in the same energy range. Since the momentum distributions of the returning electron wave packets are essentially identical (up to a normalization due to the different tunneling ionization rates) for the same laser pulse, as shown in Fig. 3(b), the differences in the electron energy spectra are attributed to differences in the DCS at large angles among the three targets. In Figs.

3(d-f) their DCS are shown for the relevant range of p_r . Note that they cover the same range of magnitude, but at large angles, say 160° - 180° , the DCS for Xe behaves “anomalously” for it increases with increasing energies instead of otherwise, as in Ar and Kr. Since higher returning energies contribute more to the plateau electron yields (see Fig. 1), this “anomalous” energy dependence explains the flat plateau in Xe. Likewise, the “normal” energy dependence of DCS in Ar and Kr can be used to explain the steep drop of their electron spectra at high energies, see Fig. 3(a). We comment that the QRS results shown in Fig. 3(a) are again in good agreement with those obtained from TDSE.

According to the QRS model, for different lasers with identical U_p , their returning electron wave packets will have the same range of kinetic energy, thus similar plateau electron momentum and energy distributions. In Fig. 3(c), we show the electron spectra for Xe using 800 nm and 400 nm lasers, respectively, but with the latter having four times the peak intensity. The spectra in the plateau region indeed agree quite well quantitatively after they are normalized to each other at around $10U_p$. Both results are obtained from solving the TDSE.

We also comment that the QRS model is based on the rescattering theory, thus it would fail at lower intensities in the multiphoton ionization regime. In Fig. 3(c) we show the comparison of results from TDSE and from QRS at two lower laser intensities, with Keldysh parameters of $\gamma = 1.59$ and 2.24 , respectively. We see clear evidence of the failure of the QRS model at $\gamma = 2.24$. This sets a rough upper limit for the validity of QRS at γ near about 2.0 .

The above examples illustrate that the behavior of laser-induced plateau electrons with energies from $4U_p$ to $10U_p$ are determined by electron-ion elastic scattering cross sections for **free** electrons with energies between $1.24U_p$ and $3.17U_p$ (or momentum between 0.79 - $1.26A_0$). Flat plateau is expected when the DCS at large angles (close to 180°) increases with increasing kinetic energy and when they are highly peaked at large angles, as in the case of Xe [Fig. 3(d)]. Such conditions occur often in the DCS in low energy electron-ion collisions. Where does it occur depends on electron energies and target species. Based on the DCS shown in Fig. 3, the plateau will become more pronounced for Ar and Kr, but less so for Xe, as the laser intensity is decreased. This is consistent with earlier experimental results [4].

In summary we studied laser-induced high-energy plateau electrons. Together with our previous results where the species dependence of HHG was traced to their

photo-recombination cross sections [10, 14, 15], we now have established a quantitative rescattering (QRS) theory for laser-induced ATI electron and HHG spectra in the plateau region. Based on the QRS model which is valid in the plateau region, there is no need to solve TDSE directly. For HHG one only needs to calculate photo-recombination cross sections and for plateau electrons one needs only to calculate elastic electron-ion scattering cross sections. The returning electron wave packets, as shown previously [13, 15], can be extracted from a companion target or from the second-order strong-field approximation. Conversely, the QRS theory allows one to extract electron and photon scattering information from laser-induced electron spectra or HHG, respectively. As proposed elsewhere [16], these cross sections can be further used to deduce the structure of the target, thus opening up the opportunity of using infrared laser pulses for determining the structural change of a dynamic system with temporal resolution of sub-femtoseconds to a few femtoseconds.
